If you are recording @ 24 bit you really don't need to get that high. Peaks of -25 to -15 are more than enough. Terry Manning of Compass Point Studios (AC/DC, ZZ Top etc) turned me on to this on a different forum and is a big advocate of it. I tried it. I have to agree with him that it made a significant improvement in the resulting sound of the recording.

also on that thread,

Actually I was reading the book lastnight and it stated that a 24bit recording at -48db is equal to a full range 16bit recording .. mind you, I was quite drunk lastnight (Twisted Evil) so someone correct me if I miss-quoted here!

That's not true, and dont let anyone tell you it is.

You still need to get all levels as optimised as possible, as we all did with tape.

Otherwise you are not using all the bits available to you, and noise will be the end result.

This is why the good/great engineers are what they are...they make sure the levels are hot...just not to the stage of distortion.

it's a balancing act, but, hey, who said anything done properly is easy.

Martin, so do you know anything about the Cubase mix bus? Do they maybe mean that on mixdown you pull the faders way back but still record hot? Just wondering how the Cubase mix bus behaves.

Thanks

Can't tell you anything technically about the Cubase mix bus, (I use Nuendo),but I think it's basically the same, but it's a fallacy that if you record at lower levels you are protecting the file from clipping. What you are doing is not using all the "bits" available to you, and therefore start introducing unwanted artifacts into the mix. If the "bits" aren't there on the original recording, and the levels are consistently low at the mix bus, no matter what you do, you can't get those

bits back and the resolution and "size" of your mix has to suffer.
I record as hot as I can, and use the channel faders to mix, usually never moving the master fader, although having said that, my mixes for TV/ Doco work are not quite as complicated as most decent size music mixes would be.

hi martin

I think what john is referring to is what started this thread. We are trying to emulate the way paris handles files at mixdown, not at recording files, at mixdown.

chuck said that paris automatically and transparently cuts channel levels by -22db, and then adds it back automatically when it hits the submix bus much the way analog consoles do.

what we were toying with is if was possible to emulate that *effect* with other daws by cutting channel levels 22db and making it back up at the output bus.

what we dont know is how cubase/nuendo mix bus handles the files.or exactly how paris does it for that matter.

If we can duplicate the way paris handles the mix bus DJ can sleep nights again .

I agree with Martin completely. To add my own general opinion on this long running "sound of summing" debate, that is fast become urban legend:

I think it is time to start debunking some of the fables around digital summing. Paris cutting levels and then adding the gain back at the master does one and only one thing: pushes all tracks down by 22dB to make it easier to sum them well below 0dBFS, and then make some of it back before the master so you didn't know what happened. If you are mixing properly in any native DAW, you will in effect do the same thing - lower track levels such that the peak of the summation remains below 0dBFS.

In simple math terms:

1- Native DAW: $2+2=4$

2- Paris: $((2-1)+(2-1)) + 2 = 4$

With SX you adjust the gain yourself on the way in, if you like, or better yet, set the levels for the mix at hand as needed, as you go.

So why do this in Paris? I am guessing Paris had to convert all audio to 24-bit if sent to the native cpu for native plugins in order to prevent clipping before you even start dropping faders on the mix (unless they somehow converted to 32-bit float on the EDS chip first, which isn't a 32-bit float chip, so that seems unlikely). (No one would want to mix with most faders at -40dB - it would "seem" wrong). 24-bits for any portion of summing (not tracking) is a limitation esp. if tracked audio files are near 0dBFS to begin with - there is no where to go with gain addition, and only subtraction to work with. You can add a lot more -22dB peak audio files to a mix without clipping (with all faders at 0), where only 2 audio files peaking just below 0dBFS will automatically clip. At least that seems to be the reasoning behind it, but imho, only applicable to prevent a potential problem in the DAW itself, not as prescribed digital audio practice.

Back to native DAWs: While this approach may seem somehow capable of producing a different sound to a final mix, the only thing you gain by lowering tracks by 22dB from the start is lower bit resolution. This is especially true if you happen to record your tracks at lower levels (e.g. -10dB peaks, then your peaks are now at -32dB, which is 1/3 the resolution of 16 bit audio - that isn't insignificant). So, if you combine the flawed advice to record at -10 to -20dB, with the concept of lowering all tracks by 22dB before you start mixing, and you end up removing most of the resolution we work hard for with quality mics, preamps and converters, and mixing as much more noise and quantization error than necessary.

As Martin suggested, record just below, or comfortably below clipping (as the source dictates) to maximize your use of bit resolution - e.g. keep audible that ambience or depth of the recording that tails off down at those lower levels, rather than mixing it with mic self-noise, etc.

John, what I think the reference you quoted is actually saying (or should be at least) is just that 24-bit digital (with a quality front end and converters) affords a higher signal to noise ratio than analog did, so pushing record levels to widen the gap between peaks and the noise floor isn't as critical. But since quite a few really great mics have a noise floor of around -70 to -74dB, we are still putting noise into half of the bits of that glorious 24-bit range.

In terms of signal vs. noise - why record less signal when you can record

more?

Imho, there are a lot of "famous" engineers out there spouting complete technical rubbish out of lack of true knowledge, or passing along conversational heresy and conjecture. Sadly, engineering is becoming more about letting the gear dictate the recording process than the engineer, and I believe that's what's wrong with music today. Too many people think xyz piece of gear can make a hit, a vibe, or a certain sound just because someone else did it, but few actually use their skills to create the sound by knowing what combinations of gear will help get them there.

9/10 times it isn't about obtaining one piece of gear to get "that sound", but understanding the 1000 different possibilities and knowing how to use any of them.

The Nuendo and SX audio engines are identical. They also are identical in summing to Sequoia/Samplitude, and probably Logic, Audition, and DP too (I've tested Nuendo and Sequoia beyond the limits of normal recording to verify this, so this comes from experience and listening, not speculation or internet urban legend).

Regards,
Dedric

Hi Dedic

Thank you for your excellent posts and the time taken on this topic. I appreciate it.

As far as specific math goes, there is one statement from the link John referenced that contradicts your statement regarding resolution at various levels

Your quote here:

" if you happen to record your tracks at lower levels (e.g. >-10dB peaks, then your peaks are now at -32dB, which is 1/3 the resolution >of 16 bit audio - that isn't insignificant). "

The other statement said that 24bit recording at -48db is equal to a full range 16bit recording...

These 2 statements look like they're talking about the same thing (apples to apples). If they are, how are they reconciled? If they're not and I'm misunderstanding...

Ted

Great post, Dedric! BTW, "The Sound of Summing" - wasn't that a
song by Summon & Nullfunkel?

Anyway, a couple of things I wanted to bring up. You said:

>In simple math terms:

>1- Native DAW: $2+2=4$

>2- Paris: $((2-1)+(2-1)) + 2 = 4$

>With SX you adjust the gain yourself on the way in, if you like, or better

>yet, set the levels for the mix at hand as needed, as you go.

I just wanted to point out that if anyone thought I meant to adjust your levels "on the way in" (i.e.: using the Channel input trim control), when I had said to default all your channels to -6, for example, as a starting point - that I did NOT, in fact, mean the input trims!!! I meant the regular ol' "please make it louder or softer" control. :D

>So why do this in Paris? I am guessing Paris had to convert all audio to
>24-bit if sent to the native cpu for native plugins in order to prevent
>clipping before you even start dropping faders on the mix (unless they
>somehow converted to 32-bit float on the EDS chip first, which isn't a 32-bit
>float chip, so that seems unlikely). (No one would want to mix with most
>faders at -40dB - it would "seem" wrong). 24-bits for any portion of
>summing (not tracking) is a limitation esp. if tracked audio files are near
>0dBFS to begin with - there is no where to go with gain addition, and only
>subtraction to work with. You can add a lot more -22dB peak audio files
to
>a mix without clipping (with all faders at 0), where only 2 audio files
>peaking just below 0dBFS will automatically clip. At least that seems to
be
>the reasoning behind it, but imho, only applicable to prevent a potential
>problem in the DAW itself, not as prescribed digital audio practice.
>
>Back to native DAWs: While this approach may seem somehow capable of
>producing a different sound to a final mix, the only think you gain by
>lowering tracks by 22dB from the start is lower bit resolution. This is
>especially true if you happen to record your tracks at lower levels (e.g.
>-10dB peaks, then your peaks are now at -32dB, which is 1/3 the resolution
>of 16 bit audio - that isn't insignificant). So, if you combine the flawed
>advice to record at -10 to -20dB, with the concept of lowering all tracks
by
>22dB before you start mixing, and you end up removing most of the resolution
>we work hard for with quality mics, preamps and converters, and mixing as
>much more noise and quantization error than necessary

Which is why I suggest starting at -6... maybe -10 if you're going to be loading up a buttload of tracks. Think about it with an analog analogy again, gang: If your analog mixing console goes up to +10 on each channel, would you start a mix with every fucking fader maxed out at +10??? Hit "play", and how would THAT summing buss sound right about then? No, to start out with, you'd bring all the faders down to 0, or -5, or -10, or whatever the your comfortable starting point was, knowing the console & how much headroom it's got, etc., right? Pushing everything up to +10 to start off with would be just

simply way too much, yes?

So why are people not willing to get their heads around the fact that in digital anything past "0" is "way too much"?

The only reason your DAW has +6 or +8 on any given channel is in case you fuck up & record the cowbell track on your band's cover version of "Mississippi Queen" at peak levels of -17db "0" gain on the channel level just wouldn't cut it at that stage, the cowbell just wouldn't be audible enough to drive that tune. :D

So, just like in the analog console, where 40+ channels recorded to needle-bending levels on overbiased tape machines, and every channel set to +10 at the start of your mixdown session would sound like crap; so does 40+ channels recorded to nice hot levels, barely missing overs by a tenth of a db, with every channel set to "0" result in a similar thing.

Neil

Hi Ted,

16 bit and 24 bit both only represent up to 0dB full scale (FS). The dynamic range afforded by 24-bit extends down to -144dB rather than the -96dB of 16 bit. That's what we are interested in with digital audio, not the theoretical limits above 0.

Once in the DAW, -48dB is represented by the lower 8 bits in 16-bit words, and the lower 16 bits in 24-bit words. That's probably how they came to that conclusion, but it's mathematically incorrect since the same bit actually represents -48dB, you just add an extra 8 onto the bottom of the dynamic range, not the top as the quote seems to assume.

Regards,
Dedric

Ah, now, this is where people get confused.

The assumption that FULL bits (all 1111's) represents 0dbfs, and that empty bits (all 00000's) represents the noise floor is false.

The full bits actually represent the maximum positive amplitude, and the empty bits represent the maximum *negative* amplitude of the bi-phase audio signal. (I have attached a pic below of a 4 bit signal capture, the vertical axis shows the 4 bits, while the horizontal axis shows the sample rate)

So, what is actually happening in 24 bit vs 16 bit is that there are more bits to represent the vertical axis. This means that "no signal" on the input of the recorder would yield a number half way up, not all zeros.

Does this help?

David.

Yah, I was referring to the sampling phase of straight PCM encoding. I don't even want to know what goes on after that! Geek!! ;-)

David.

See now it get's even more confusing....

Why? Check any math text, sine wavs are always represented with signed numbers, doesn't matter if it is integer or float.

Even if there is no sign bit on the platform, we fake it by splitting the highest possible value for a word size in half just to link what we are doing to the math world.

Positive amplitudes are positive numbers, negative amplitudes are negative numbers, and zero, most definitely is silence :-)

So... In a sense you are right, but your graph is wrong :-)

Chuck

I think I have clouded the issue. No, wait, I know I have. ;-)

Chuck is right about how bits are translated to amplitude representations, and I knew this to be the case, but when talking about dynamic range we are talking about power in terms of dBFS. Here we don't refer to the +/- aspect of amplitude, but rather signal power only relative to 0dBFS (power is an absolute value since negative power is only theoretical); but, since the maximum value chosen for digital is 0dBFS, we use negative dB values to represent the power range of the signal.

So in actuality, all 1's (sign bit excluded) represent the maximum amplitude of the signal which can be a + or - amplitude, in absolute value, (which translates to 0dB Full Scale digital, but not 0db!), and all 0's represent 0db actual power level ("silence", aka anything below -96dB for 16 bit and -144dB for 24-bit - correct Chuck?).

Since audio is quantized into the word based on voltage, not power, 1.1 volt (I believe this is standard) is given the reference level of 0dBFS at the ADC. So in effect, 24-bits provides better resolution as we approach 0 volts, and 0db in signal power, than 16 bits. The dynamic range is a relative value. 16 or 24-bit words are actual signed values for voltages between 0 and 1.1 volts. The area under that point in the curve is where we get power but that is inverted to create the dB digital range in steps of -6dB per bit from 0dBFS down. So, adding 8 bits to a 16 bit word doesn't decrease the power step size to less than 6dB per bit, but rather extend the power range down an extra -48dB to -144dB - just a matter of detecting lower voltage levels at the ADC so we get better sensitivity in the recording, not the headroom to record louder drummers. ;-)

Do you guys agree with this explanation or is that even more convoluted?

Regards,
Dedric

I must be confused too neil .

I thought that with a 0dbfs wave ,the positive peak of the wave would have
a word value of 1111111111111111 and the negative peak word was
0000000000000000. with a 16 bit word

Yes with amplitude you get greater resolution with higher bit depths (more
levels to quantize each sample). This isn't the same as the dynamic range
though.

For each extra bit added, we basically reduce the quantization noise by
6dB - we halve the distance between quantization levels (doubling the number
of quantization levels for that same range of amplitude - 0v to 1.1v).
Since power ratio (dB) is a log function we get a consistent change of

relative power of 6dB for each halving of the distance between quantization levels (when referring to the quantization noise floor - 6dB is also often used to refer to "twice the loudness" - but whether you are referring to 6dB as lowering noise or raising volume the power change is the same, but with digital audio we are referring to lowering quantization noise, not doubling the "loudness" with each bit).

So, dB is a measurement of power ratios (change in power).

$$\text{dB} = 10 \cdot \log_{10}(P2/P1)$$

where P1 is the power being measured, and P1 is the reference to which P2 is being compared.

Likewise, voltage ratios are:

$$A = 20 \cdot \log_{10}(V2/V1)$$

So the dynamic range increases by 6dB with every bit we add (by lowering quantization noise with twice the quantization levels), and in the digital realm, the reference is 0dBFS so the range (really "depth") extends down from there as we push the quantization noise lower and lower (hence -144dB for 24 bit). Amplitude level changes are more accurately represented by more bits since we have more levels to depict each level between 0v and 1.1v, but the 0 to 1.1voltage range never changes in the converter whether it's a 4 bit or 24 bit converter (of course the max 1.1 volts may vary depending on the converter application, design and analog input transform, but with audio I believe 1.1v is most common).

Anyone else feel free to add or expand on this. I may have still missed some informative bit of techdom, or mis-stated something, considering how I originally turned this murky water into thick mud. ;-)

Actually for 16 bit, the positive peak is 0111111111111111, and the negative peak is 1000000000000000 in signed 2s complement binary. 1 sign bit on the far left. In sign and magnitude, the positive peak is 0111111111111111 and the negative is 1111111111111111.

0 is 0000000000000000 in both cases. Only binary offset puts 0000000000000000 at the most negative peak, but that isn't used in digital audio (just fyi).

dedric:

so if we use 32 bit floating point math, the quantization error created by the software data processing will be eliminated?or were you referring to errors created at the converters?

Thanks Dedic-

Either the author made the mistake you've postulated, or the author was misquoted.

Thanks again, the people on this newsgroup (like you) make it the great place to hang out that it is - virtually speaking :)

Yes, that's what I meant, and it's linear, right? In other words, if a sine wave is full-on 0db flat-out at peaks, then (in a simplistic example) 12 bits are taken up in half that amplitude, and 12 bits are taken up in the remaining half, or 6 bits are taken up in a quarter of it, and so on, right?

>This isn't the same as the dynamic range though.

Ooooooooooh, ok, now I'm confused again.

If you're recording at a low level... let's say peaks of -40 or -50 db on a given track, chances are you're only using 12 or so bits of that file capacity even though you may be "recording" at 24-bits, yes? Or are you saying because db is log, not linear, you might actually be only using 6 or so of your available bits if you're recording at those low peaks of -40 or -50?

If all mix busses are the same, why did the PT III rigs suck out loud so badly unless you kicked the master fader down to -15db/-20db?

That's why I referred to native summing - most native apps (all but Saw Plus) are 32-bit floating point.

ProTools is hardware hybrid like Paris so I categorize them differently. The earlier systems (through Mix+) used a 24-bit data path with no dither, until they added the dither mixer somewhere in the Mix+ lifecycle, so in that case you really did lop bits off the bottom when dropping the fader. The dither engine slightly improved things, but not the lost bits (may have added a double precision summing section - don't recall specifically). Still the 24-bit buss was still a big problem.

The only reason PTHD sounds better is they doubled up the processing path to 48bits, but it's the same 24-bit dsp chip family they seem to be stuck with.

Dedric

ok now i know what you were getting at. i guess i have to follow these threads closer. skip one or two and i get lost.
thanks dedric

Plus, those 888 convertors sucked hind tit - that sure didn't help matters, summing issues or no.

>The only reason PTHD sounds better is they doubled up the processing path to 48bits

And the newer Digi convertors really do sound good - start with crap, end with crap - highly polished crap, but crap nonetheless. Start with something good - it's up to the user to fuck it up from there! LOL

I knew that a cowbell would somehow ind it's way into this.

Do you know, my E-MU 1212M and new 1616M PCI cards has the same converters as PTHD, A/D convertor is AK5394A and D/A convertor is CS4398, sounds real good for not colored hi-end stuff. Very cheap too, \$199 with bundle of SOANAR LE, Cubase LE, Ableton Live Lite 4, Wavelab Lite and other cool stuff like Proteus X LE. But I think 1212M is now not supported, sounds familiar, yes?
